Phylogenetic analysis

**A B S T R A C T**

A new microsporidium was isolated from *Ocinara lida* Moore (Lepidoptera: Bombycidae), a pest of *Ficus microcarpa* L. f. in Taiwan. The microsporidium produces systemic infections in *O. lida* larvae; the midgut epithelium, Malpighian tubules, and midgut muscle tissues were the target tissues for this isolate, and atrophied fat body tissues were found in heavily infected larvae. Two types of spores were observed, diplokaryotic spores with 11–13 coils of polar tube, and monokaryotic spores with 12 coils of the polar tube that developed within a sporophorous vesicle to form octospores. Electron-dense granules were abundant in the episporontal space of the sporophorous vesicles, and were similar to those of *Vairimorpha invictae* isolated from *Solenopsis invicta*, but different from granules or inclusions of other *Vairimorpha* species. Based on the phylogenetic analysis of the small subunit ribosomal DNA sequence, this isolate is unique within the *Vairimorpha* complex. Morphological and genetic characters showed this isolate to be a new species. It is placed in the genus *Vairimorpha* and is described as *Vairimorpha ocinarae* n. sp.

1. Introduction

Microsporidia are eukaryotic organisms that parasitize nearly all groups of animals (Canning and Lom, 1986). Lepidopteran larvae with microsporidiosis are commonly found in the field, and most of these microsporidia are classified into three genera, *Endoreticulatus*, *Nosema*, and *Vairimorpha* (Solter et al., 2000). Phylogenetic analysis of the small subunit ribosomal DNA (SSUrDNA) shows the genus *Endoreticulatus* to be a distinct clade (Wang et al., 2005), but the genera *Nosema* and *Vairimorpha* could not be separated into different clades using molecular characters (Ku et al., 2007; Tsai et al., 2003). The genus *Nosema* is defined as polyphyletic according to phylogenetic analyses, but *Nosema* and *Vairimorpha* are traditionally differentiated using morphological characteristics (Pilley, 1976). The life cycles of species in the genus *Vairimorpha* are more complex than those of *Nosema* spp. After the genus *Vairimorpha* was described by Pilley (1976), several microsporidian species were reassigned to this genus based on the production of two types of spores, diplokaryotic single spores and monokaryotic octospores (Pilley, 1976; Vavra et al., 2006), the latter being the apomorphy for the genus *Vairimorpha*.

In 2006, fertilized females of *Ocinara lida* Moore (Lepidoptera: Bombycidae), a pest of *Ficus microcarpa* L. f., were collected near the campus of National Taiwan University and were reared in the laboratory. The microsporidian infections in the offspring were systemic and led to the collapse of the entire laboratory population. Observations of the infected tissues and pathogenesis showed this microsporidium to be different from the *Endoreticulatus* sp. that was previously recovered from the same host (Wang et al., 2005). In this paper, we describe this new isolate based on analysis of the SSUrDNA sequence and ultrastructural characteristics.

2. Materials and methods

2.1. Host insect and microsporidian isolate

Inseminated female *O. lida* moths were collected on the campus of National Taiwan University in Taipei, Taiwan. The moths were allowed to oviposit and the resulting larvae were reared on leaves...
of Ficus microcarpa L. f. in the laboratory at ambient room temperatures (approximately 29 °C day, 12 °C night). Fourth- and fifth-instar larvae were dissected and tissues (midgut, fat body, and Malpighian tubules) were microscopically examined. Larvae with microsporidiosis were stored at 4 °C.

2.2. Spore purification and DNA extraction

Infected host tissues were homogenized, filtered and centrifuged to purify mature spores from spores as described previously (Tsai et al., 2003; Wang et al., 2005). The purified spores were stored in the TE buffer (0.1 M Tris, 0.01 M EDTA, pH 9.0) at 4 °C. The spore solution (10⁶ spores in 0.5 ml TE buffer) and an equal volume of zirconia silica beads (0.1 mm diameter) were mixed in a 10 × 75 mm glass tube and shaken at maximum speed on a vortex machine for 1 min (Undeen and Cockburn, 1989). The solution was treated with proteinase K and the DNA was extracted using a QIAamp DNA Mini Kit (Qiagen, Hilden, Germany) according to manufacturer’s instructions. The DNA was eluted in ddH₂O and stored in –20 °C. DNA concentration and quality were measured on a GeneQuant pro spectrophotometer (Amersham, Bioscience).

2.3. Amplification and sequencing of SSUrDNA

The primer set (18F: 5'-CAGACGGTTGATTCGCC-3', 5'-TTATGATCTGTAATGGTTC-3') was used to amplify SSUrDNA (Vossbrinck et al., 1987, 1993). The total volume of PCR is a 100-μl reaction containing 100 ng of DNA, 10 mM Tris–HCl, pH 9.0, 50 mM KCl, 1.5 mM MgCl₂, 200 μM of each dNTP, 100 pmol of each primer, and 2.5 U HiFi DNA polymerase (Yeastern Biotech). The amplification was performed in an AG-9600 Thermal Station (Biotronics Corporation) for 40 cycles, each with the following profile: 94 °C for 30 s, 50 °C for 30 s, and 72 °C for 90 s. A 10 μl aliquot was run on a 1.0% agarose gel to visualize the PCR product. The DNA fragments were cloned into T&A cloning vector (RBC, Bioscience) and both DNA strands were sequenced on an automated DNA sequencer (DNA sequencer 377, Applied Biosystems).

2.4. Phylogenetic analysis

The SSUrDNA sequences of the O. lida microsporidium were compared to Nosema and Vairimorpha sequences in GenBank (Table 1) for phylogenetic analysis. All sequences were aligned using the “Clustal X 1.18” program (Thompson et al., 1997) and then manually edited with the GeneDoc program (Nicholas et al., 1997). Encephalitozoon cuniculi was used as the outgroup. The analyzed sequences were initiated with random starting trees, then run for 1 × 10⁶ generations and were sampled every 100 generations. The burn-in period discarded 1000 generations. Posterior clade probabilities were used to assess nodal support. Tree topology was represented on the 50% majority-rule consensus trees.

2.5. Cytological preparations

2.5.1. Light microscopy

Malpighian tubules, midgut and fat body tissues from infected hosts were individually smeared on slides, observed under phase-contrast microscopy (Olympus IX71), and photographed using a CCD (Olympus DP70) camera. Spore size was measured by Amira 3.1.1 program (for MacOSX).

2.5.2. Transmission electron microscopy

The infected tissues were fixed for 2 weeks in 5% glutaraldehyde in a 0.1 M phosphate buffer (pH 7.2) and postfixed in 1% OsO₄ for 2 h (Wang et al., 2005). The tissues were then dehydrated in an ethanol gradient series and the samples were embedded in EMBed 812 (Electron Microscopy Sciences). Thin sections were cut on a Reichert OMU 3 ultramicrotome and stained with uranyl acetate and lead citrate. The micrographs were taken with a Hitachi H7100 electron microscope operated at an accelerating voltage of 80 kV.

3. Results

3.1. Gross pathology

In the early stages of infection, there were no obvious signs or symptoms of disease. In the late stages, the infected larvae showed obvious signs, including changing of body color from brown to light yellow-brown and increasing transparency of the abdominal integument. In addition, the infected larvae exhibited symptoms such as vomiting and diarrhea. Microsporidian spores could be observed using phase-contrast microscopy in the fluid vomit and feces. In the late stages, the entire gut of infected larvae was swol- len, light yellow-brown in color, and filled with fluid. The Malpig- hian tubules were white to light pink, and the fat body was atrophied. Eventually, the larvae died, with the soft tissues gath- ered to the posterior half of the body producing a balloon-like appearance.

3.2. Phylogenetic analysis of SSUrDNA

The SSUrDNA gene of Vairimorpha ocinarae consisted of 1248 bp, and the GC content was 36.78%. Based on SSUrDNA sequences, two genera, Vairimorpha and Nosema, formed a complex in the maximum likelihood analysis (Fig. 1). V. ocinarae was unique and shared the same ancestor with other species within the Vairi- morpha complex. The identities of SSUrDNA sequences between V. ocinarae and other species within the Vairimorpha complex were 96–98%. Identity between V. ocinarae and the type species of the genus, Vairimorpha necatrix, was 96%. The identities between V. ocinarae and other species within the Vairimorpha complex were 96–98%. Identity between V. ocinarae and the type species of the genus, Vairimorpha necatrix, was 96%.
narae and Nosema species within Vairimorpha complex were 97–98%, but were 81–82% between V. ocinarae and species within the 'true' Nosema complex (type species Nosema bombycis. All Vairimorpha species analyzed were parasites of lepidopteran insects with the exception of N. oulemae, which was isolated from a coleopteron. The distance matrix is shown in Table 2. The shortest distance was found between V. ocinarae and N. carpocapsae.

3.3. Morphological characteristics

3.3.1. Light microscopy

Because the host larvae were infected transovarially, the primary sporulation cycle (S1 cycle; Vavra et al. 2006) reported in most recent Nosema and Vairimorpha species descriptions was not observed. The fresh single diplokaryotic spores of the secondary sporulation cycle (S2ss) were elongate-oval in shape, refractive under phase-contrast microscopy (Fig. 2), and abundant in the epithelium of midgut and Malpighian tubules. Fresh, mature S2ss spores measured $4.17 \pm 0.25 \times 2.34 \pm 0.13 \mu m$ (mean ± standard error, $n = 50$). Octospores produced in the octosporous secondary sporulation cycle (S2oct) were found in the midgut muscles (Fig. 3) and fresh mature spores measured $2.62 \pm 0.3 \times 1.39 \pm 0.18 \mu m$. Cyst-like structures (33.55–48.19 $\mu m$ in diameter) (Fig. 4) were commonly seen in the gut tissues but not in other tissues. We were not able to determine if these structures were actually cysts or were individual cells filled completely with spores.

3.3.2. Transmission electron microscopy

3.3.2.1. Diplokaryotic secondary spore sporulation cycle (S2ss). The microsporidium completed the S2ss cycle in direct contact with the host cell cytoplasm in all tissues, primarily in the gut epithelial tissues and the Malpighian tubules. All developing stages were observed in these tissues, however, asynchronous development of V. ocinarae in individual infected cells was observed. In the early stage of S2ss merogony (Fig. 5), the meront was round in shape and possessed a homogenous light-staining cytoplasm. No dominant endoplasmic reticulum (ER) or Golgi vesicles were observed in the cytoplasm. Host mitochondria were observed surrounding microsporidia in the early merogonial stage. In the late stage of S2ss merogony, the meront cytoplasm was filled with ER structures (Fig. 6). The S2ss meront then divided into two diplokaryotic cell products.
sporonts by binary fission (Fig. 7). A thickened plasmalemma surrounded the S2ss sporonts and obvious ER structures were observed (Fig. 8).

The exospore of the mature S2ss spore (Fig. 9) presented as an undulating electron-dense layer, 24.4 nm thick on average. The endospore was an electron-lucent layer 77.7 nm thick on average, except at the anterior part of the spore. The anchoring disc and straight portion of the polar tube formed a mushroom-shaped structure at the anterior part of the spore. The polaroplast was not well fixed for transmission electron microscopy but was observed to be divided into two parts. The anterior portion was more electron-dense than the posterior portion (observed directly behind the lobes of the anterior portion). Many small bubble-like forms (63.7–69.7 nm in diameter) were observed in the posterior vacuoles (Fig. 10). The polar tube was isofilar with 11–13 coils (typically 12 coils) arranged in a single row. The diameter of the polar tube was 90.8 ± 7.4 nm, and many concentric layers were seen in transverse sections (Fig. 11).

3.3.2.2. Octosporous secondary sporulation cycle (S2oct). The octospores produced in the S2oct cycle were observed only in the muscle tissue of alimentary canal, and were not found in the midgut epithelium or Malpighian tubules. In the muscle tissues, the microsporidium primarily exhibited the S2oct sequence rather than the S2ss sequence, but all stages of the two different sequences could be observed in these tissues. In the initial stage of the S2oct cycle, a binucleate sporont was surrounded by a thin, electron-dense envelope to form a sporophorous vesicle (SV). The cytoplasm of the S2oct sporont was rich in ER and aggregated ribosomes (Fig. 12). Electron-dense granules were accumulated in the episporontal

Fig. 5. Transmission electron micrographs of secondary single (diplokaryotic) sporesporulation cycle (S2ss) of Vairimorpha ocinarae. An electron-lucent binucleate S2ss meront surrounded by host mitochondria (MT). N, nucleus. Scale bar, 500 nm.
space, the space between the parasite and the SV envelope, and
electron-lucent tubule-like structures were interspersed among
the granules (Fig. 12). The binucleate S2oct sporont divided to form
uninucleate sporonts, each surrounded by a thin plasmalemma
(Fig. 13).

Two stages of plasmodia were observed within the SV and ap-
peared to have different structures: (1) plasmodia with loosely
stacked lamellae in the episporontal space: the plasmalemma of
the plasmodia extruded large quantities of electron-lucent tu-

bule-like structures (Fig. 14) that formed channels from the S2oct
sporonts to the host cytoplasm (Fig. 14A and B); and (2) multinu-
clear plasmodia with the thin plasmalemma enveloped by an out-
side electron-dense layer. Tubule-like structures budded from the
plasmalemma, and the distal ends of these electron-dense tu-
bule-like structures were covered with another electron-dense
substance (Fig. 15A and B). In cross-section, the tubules were
75.4 nm in diameter (Fig. 15B). In this plasmodial form, electron-
lucent tubules also formed channels connecting to the host cytoplasm (Fig. 15A).

The S2oct sporonts were enveloped by electron-dense layers and each lobe contained one nucleus (Fig. 16). A few large and regular electron-dense granules were surrounded with lamellae in the episporontal space (Fig. 17). Irregularly shaped S2oct sporoblasts were observed in the SVs, and the number of electron-dense granules apparently decreased in the episporontal space during development of sporoblasts (Fig. 18). The sporoblast (Fig. 19A) possessed an electron-dense coat with a sandwiched structure consisting of a thin electron-moderate outer-layer (8.3 nm), a thick electron-dense mid-layer (58.6 nm), and an electron-lucent inner-layer (16.3 nm) (Fig. 19A). Lamella-like structures (35.6 nm) formed within the SV during this period consisted of three layers, two electron-moderate layers of approximately equal thickness sandwiching a very thin electron dense layer (6.1 nm) (Fig. 19B). In addition, the developing polar tube was observed. Unsynchronized development of S2oct sporoblasts in the same SV was also observed (Fig. 19). In the later sporoblastic stage, irregular groups of transversely sectioned coils of polar tube were arranged at the mid-posterior area of the sporoblasts, and a large empty space surrounded each sporoblast within the SV, possibly due to shrinkage in size of the maturing spores (Fig. 20). The mature octosporidium possessed a three-layer arrangement of polar tube coils (8–9 coils), one nucleus, the polaroplast, and a thick spore wall including an electron-lucent, thick endospore wall approximately 84–125 nm thick, and an undulating layered thin exospore wall approximately 34 nm thick (Fig. 21).

4. Discussion

Two genera of microsporidia, an *Endoreticulatus* species from Taiwan that is closely related to *E. schubergi* (Wang et al., 2005), and *V. ocinarae* described in this study, have been isolated from *O. lida* collected from different sites in Taiwan. The two microsporidian isolates are easily differentiated based on the number of nuclei contained in the mature spores, tissue tropism, and molecular sequence (SSUrDNA). *V. ocinarae* produces both diplokaryotic single spores and monokaryotic octospores in a sporophorous vesicle, and infection is systemic in the host. In contrast, *Endoreticulatus* sp. infects only midgut tissues, is uninucleate in all stages, and devel-

**Fig. 13.** Electron micrographs of *Vairimorpha ocinarae* in the early stages of octosporous secondary sporulation cycle (S2oct). Two sporophorous vesicles containing three visible monokaryotic sporonts (SP). Scale bar, 500 nm.
ops in a parasitophorous vesicle. It is not uncommon to recover microsporidia from different genera in the same host; for example, microsporidian species belonging to the genera *Endoreticulatus*, *Nosema*, and *Vairimorpha* were isolated from different populations of *Lymantria dispar* in Bulgaria (Solter et al., 2000) and other areas in Eastern and Central Europe (McManus and Solter, 2003).

The gross pathology of *V. ocinarae* differs appreciably from those of other lepidopteran *Vairimorpha* spp., including atrophy of the fat body tissues, swelling of gut tissues, and whitish to pink color of the Malpighian tubules. Typically, the fat body is the primary target tissue for lepidopteran *Vairimorpha* species, and cells are often hypertrophic and filled with both diplokaryotic spores and octospores (Canning et al., 1999; Darwish et al., 1989; Mitchell and Cali, 1993; Moore and Brooks, 1992; Moore and Brooks, 1994), unlike the fat body atrophy observed in *V. ocinarae* infections.

The developmental stages of *V. ocinarae* were similar to many *Vairimorpha* species but episporontal inclusions of *V. ocinarae* were different from those of other *Vairimorpha* species (Table 3). *Vairimorpha* species have been reported to include different types of episporontal inclusions (granules), electron-dense stacked lamellae, and irregular meshwork within the episporontal space of the sporophorous vesicle (Canning et al., 1999; Mitchell and Cali, 1993; Moore and Brooks, 1992, 1994; Vavra et al., 2006). *V. ocinarae* produces a simple type of episporontal inclusions in the form of electron-dense granules, similar to those of *V. invictae* (Jouvenaz and Ellis, 1986). Large granules were observed in both *V. ocinarae* and *V. invictae*, but the tri-layer structure of the granules is described only for *V. ocinarae* (Fig. 18).

The granules of *V. ocinarae* accumulated and formed a few lamellae (Fig. 15), but they did not develop into an amorphous

mass or meshwork like that observed in *V. necatrix* (Moore and Brooks, 1992; Mitchell and Cali, 1993), *V. disparis* (Vavra et al., 2006), and *V. heterosporum* (Moore and Brooks, 1994). Moore and Brooks (1994) proposed that episporontal inclusions may be used as taxonomic features among species. In our case, episporontal inclusions of *V. ocinarae* are actually different from other related *Vairimorpha* species. Although *V. invictae* possesses similar electron-dense granules, its spore size (11.2 × 3.1 μm) and polar tube coils (24–26 coils) are different from *V. ocinarae* (Jouvenaz and Ellis, 1986). Due to the low genetic identity between *V. invictae* and *V. ocinarae*, *V. invictae* was not analyzed in the phylogenetic tree of SSUrDNA. It was previously shown that *V. invictae* is not closely related to other *Vairimorpha* species, including *V. necatrix* (Moser et al., 1998).

The correlation between episporontal inclusions and phylogenetic relationships among species in the *Nosema*/*Vairimorpha* complex is probably low. *V. imperfecta* exhibits an abortive octosporous sporogony, and produces electron-dense tubules and network of electron-dense materials in the episporontal space (Canning...
cies (Canning et al., 1999; Moore and Brooks, 1992, 1994). The elec-

tron-dense tubules of *V. ocinarae* extended from the plasmodial surface and terminated beneath the SV envelope. They followed a slightly helical course and may play a role in the maintaining the functional link between the parasite and the host cytoplasm, possibly a pathway for nutrients or signal transduction between the parasite and the host cell. In fact, we observed many pores in the SV envelope (Figs. 16A and 17A) that are the openings for the electron-dense tubules. Similarly, it was reported that the pores on the parasitophorous membrane of *Encephalitozoon cuniculi* may contribute to the exchange of materials between the microsporidium and the host (Rönnbäumer et al., 2008). The electron-dense tubules of *V. ocinarae* were round in cross-section (Fig. 16B), similar to those of other *Vairimorpha* species (Table 3). Among isolates, this characteristic may present as different types (Moore and Brooks, 1994).

Diplokaryotic (S2ss) spores of *V. ocinarae* were slightly different from those of other *Vairimorpha* species, including the size of fresh spores and the number of polar tube coils. Small bubble-like forms were observed in the posterior vacuole of diplokaryotic S2ss spores of *V. ocinarae*; similar structures were not reported from other *Vairimorpha* species. *N. portugali* possesses similar structures, but these forms were not observed in the closely related *V. dispersi* (Maddox et al., 1999; Vavra et al., 2006). The octospores of *V. ocinarae* were smaller in size than those of other *Vairimorpha* species, and there were fewer polar tube coils (8–9 coils) than observed in other species with the exception of *V. invictae* (9 coils) (Jouvenaz and Ellis, 1986).

The phylogenetic relationships between *V. ocinarae* and other species within the *Vairimorpha* complex have typically been interpreted based on maximum likelihood and maximum parsimony methods (Fig. 1 and Supplementary data). Analyses showed that *V. ocinarae* is a unique species and distinct from other species in the *Vairimorpha* complex. The bootstrap values were very high (100%), but the relationships between other species within *Vairimorpha* complex were still unclear, except that *N. portugali* and *V. dispersi* both pathogens of the gypsy moth, *Lymantria dispersi* (L.) were clustered together. The high identities (96–99%) among species of *Vairimorpha* lead to low resolution using different analytical methods (Supplementary data).

In the distance analysis, *V. ocinarae* is closer to *N. carpospargae* than to other species, but the distance between *N. carpospargae* and *N. oulemae* (0.01002917) is shorter than the distance between *V. ocinarae* and *N. carpospargae* (0.01507825). Distances between *V. ocinarae* and other species in *Vairimorpha* complex were larger (Table 2). The *V. ocinarae*/N. carpospargae/N. oulemae group, and the *N. portugali*/V. dispersi group were separated in the phylogenetic analysis based on neighbor-joining method.

*Vairimorpha ocinarae* is placed in the genus *Vairimorpha* based on typical morphological characteristics of *Vairimorpha* and phylogenetic analyses of its SSUrDNA. This microsporidium was initially hypothesized to be a new *Vairimorpha* species based on tissue tropism and effects on the host, morphological characteristics and the peculiarities of electron-dense granules in ultrastructural evaluation. The results of phylogenetic analyses corroborate its assignment as a new species.

4.1.3. Site of infection
Systemic infection. Diplokaryotic spores were observed primarily in the epithelium of gut and Malpighian tubules. Monokaryotic octospores occurred only in the gut muscle tissues. Fat body tissues were not heavily infected and were atrophied.

4.2. Ultrastructure

4.2.1. Diplokaryotic secondary spore sporulation cycle (S2ss)
The S2ss meront is round in shape and possesses an electron-lucent cytoplasm. The late-stage meront is elongate and divides by binary fission to form two diplokaryotic sporonts. The S2ss spore is elongate-oval and living spores measured 4.2 × 2.3 μm. The exospore is an electron-dense 24.4 nm thick layer. The endospore is an electron-lucent layer that is, on average, 77.7 nm thick. Many small bubble-like forms occur in the posterior vacuole. The polar tube is isofilar, with 11–13 coils, most often 12. The polar tube measures 90.8 ± 7.4 nm in the diameter and consists of at least three dominant concentric layers.

4.2.2. Octosporous secondary sporulation cycle (S2oct)
At the initial stage of octosporous sporulation cycle, a uninucleate sporont is surrounded by a thin, electron-dense, sporophorous vesicle (SV) envelope to form a sporophorous vesicle (SV). The S2oct sporont divides to form the uninucleate sporonts surrounded by a thin plasmealama. The sporont develops within the sporophorous vesicle during the developmental process. The large granules were composed of three layers. Loosely stacked lamellae appeared in the episporontal space. Electron-lucent tubules and electron-dense tubules were located between the granules and the S2oct sporonts. Polar filament coils number 8–9 in the mature octospores.

4.3. Deposition of specimens
Viable spores (Accession No. 2008-C) are maintained in liquid nitrogen storage and in a 4 °C freezer in the Entomology Department Laboratory of National Taiwan University, Taipei, Taiwan. Living spores are produced in Bombyx mori every 6 months. The SSUrDNA sequence is deposited in NCBI GenBank Accession No. EU338543.
